ABSTRACT

This paper reviews issues pertaining to the relationship between child mortality and fertility and examines the fertility-mortality relationship of women who emigrated to Israel from various countries in Asia, Africa, and Europe and continued child bearing in Israel. Data from the 1961 Israel census of population is used. Among issues addressed in a discussion of the relationship between child mortality and fertility are replacement (the attempt to replace the deceased child through a new pregnancy) versus hoarding (the attempt to increase the number of offspring in response to expected mortality rates), and the degree to which child mortality affects the desired number of surviving children. Following this, cross-sectional regressions of fertility in Israel are studied as a function of fertility and mortality abroad, education and age variables. Regressions are run by separate countries of origin and pooled for Asia, Africa and Europe. Later sections use the same data to infer the temporate aggregate movements (changes that had occurred in country of birth and changes associated with immigration) in fertility and child mortality, and try to fit this together with the cross section findings. Combined results indicate a discrepancy between the cross-section and time series relationship between fertility and mortality, since an increase in fertility following immigrations, as well as a rising fertility of Moslems over time, is found. It is suggested that factors that determine child mortality and those that determine prenatal death or involuntary sterility are correlated with one another more closely in the time than in the cross section series. FERTILITY AND CHILD MORTALITY -- ISSUES IN THE DEMOGRAPHIC TRANSITION OF A MIGRANT POPULATION*

Yoram Ben-Porath

The Hebrew University of Jerusalem

A paper presented at the Universities-National Bureau Conference on Population and Economic Change in Less Developed Countries, Philadelphia September 1976.

* I thank W. Butz, J. DaVanzo, E. Van der Walle, S. Freund, S. Kuznets, J.P. Smith and A. Williams for helpful comments on earlier drafts and the staff of the Demographic Section in the Central Bureau of Statistics of Israel for providing me with the data sources. I carry sole responsibility for the paper and the data. I draw here on my work at the Falk Institute for Economic Research in Israel. The paper was prepared under a grant from the Rockefeller Foundation to The Rand Corporation.

I. INTRODUCTION

The relationship between child mortality and fertility is central to the explanation of the transition of European populations from high to low levels of fertility. The recent decline in child mortality in several less developed countries caused a renewed interest in this relationship and several cross-section studies have tried to sharpen some of the issues concerning it.

Several cross section studies found statistically significant relationships between fertility and child mortality. Some interpret the evidence as an indication of a fairly strong and rapid response that would not predict a long lag between turning points in aggregate fertility series following the onset of declining mortality (see T. P. Schultz 1975.) Others tend to view the evidence as showing modest to small response (see Preston 1975). As to the aggregate experience over time there is no dispute concerning the long and variable (across individual countries) lag in the decline in fertility relative to the decline in mortality in Europe. As far as the LDC of today are concerned, while Taylor et al. (1976) [and UN (1974)] indicate a shorter lag than historically observed, Kuznets (1974), examining the aggregate time series of LDCs, emphasizes the sluggishness in the response of fertility to the decline in child mortality.[1]

In this paper, I consider the experience of the foreign-born population of Israel from this perspective. Immigration to Israel constituted a sharp change in conditions that is a dramatically speeded-up version of economic and social development for those immigrating from the less developed countries of Asia and Africa. There is no way to assess how much the responses to a shock treatment like this can tell about processes

of more continuous change -- potentially this can either sharpen what is otherwise confounded with other things or bring out "anomalies" that would make it so unique as to be uninteresting.

The plan of the paper is the following: In Section II I briefly review some of the main issues in the child-mortality/fertility relationship. In Section III, I present cross-section regression models based on the analysis of the experience of individual foreign-born women in Israel. In Section IV, using mostly the same data, I infer what happened over time abroad and following immigration, and then try to fit this together with the cross-section findings.

II. SOME GENERAL ISSUES

Let me summarize here some of the main issues with respect to the mechanism relating fertility to child mortality. (See also Schultz 1975, Preston 1975a).

REPLACEMENT VERSUS HOARDING

The reaction of fertility to child mortality can take two forms: replacement, a sequential response to the occurrence of a death and what is described as hedging or hoarding -- the response to *expected* mortality. If mortality of offspring were only infant mortality and if there were no fecundity constraints on the number of successful pregnancies, replacement would be the superior mode of response.

The need for hoarding arises when there is a danger that the desired number of surviving children of the right age and at the right time will not be attained. Offspring who die as adults may not be replaced by the same mother because she is too old (or has died); or even if they can be replaced, they would not be available as e.g. earners contributing to family income at the necessary time. Situations like this involve uncertainty concerning the number and age distribution of surviving children along the parental life cycle. Hoarding is a natural strategy to cope with the problem, particularly if one has a view of the demand for children as being of the "at least (so many children/sons)" type. It should, however, be stressed that hoarding implies not only a higher expected cost of surviving children, but also higher risk that disposable income will be "too low" for parental or per capital consumption if the number of surviving children is *ex post* "too large." (Such a risk may be more tolerable with higher income and this may itself lead to a direct relationship between births and income, for a given level of expected child mortality.)

The distinction between replacement and hoarding is important for at least two reasons: (a) quantitatively, the effect on fertility of

hoarding in order to achieve a given target is greater than that of replacement (see O'Hara, 1972b); (b) replacement is a quick response, and it is natural to expect replacement to generate a close, short-lagged, association between fertility and child mortality. Hoarding, based as it is on expectations, may respond sluggishly to child mortality, depending on the speed at which expected mortality is revised as actual mortality changes.

Classical demographic transition, reflecting a lag of several decades before the decline in aggregate child mortality is followed by a decline in aggregate fertility, would be consistent with the importance of hoarding, but the long lag in aggregate series could result also from a combination of replacement and some countervailing forces.

The issue is whether hoarding can be quantitatively distinguished from replacement and if not, what can be said about the likely dominant mechanism behind the coefficients estimated in cross-section studies. These obvious things have to be noted: 1) To the extent that expected mortality is shared by the observation analyzed, obviously it is not reflected in fertility differences and is, thus, silent. 2) To the extent that expected mortality is strongly correlated with experienced mortality (and any attempt to estimate expected mortality will have to rely heavily on experienced mortality), it cannot be distinguished from replacement. 3) Similarly, to the extent that variables other than experienced mortality affect expected mortality, if they affect fertility also directly, the effect of expected mortality would be confounded with these direct effects. 4) Hoarding may have its larger effect on age at marriage.

In cross-sections of countries or regions or social classes, the sample observations are likely to differ in expected mortality, so that hoarding has a chance to contribute to the explanation of differential fertility. This contribution will, however, be empirically expressed through experienced mortality and other variables (schooling, income, etc.) in the fertility equation. The effect of hoarding is based on the reciprocal of surviving probability and should be larger than that of replacement; so in this type of data we should expect larger coefficients if hoarding is indeed important.

In cross-sections of households in one country all shared expectations

are, of course, silenced. If people tend to infer from excessive experienced mortality that their future children are less likely to survive, then the estimated effect of experienced mortality includes some hoarding. Obviously, some of the differences in experienced mortality are systematic, depending on permanent health and environmental characteristics of parents and households. Such factors may operate for more than one generation and reinforce the correlation between expected and experienced mortality. The variables that enter the fertility equations for other reasons will carry some of these effects. In general the correlation between experienced and expected mortality is likely to diminish as the data are more disaggregated. It is also reasonable to expect that in studies where experienced mortality and, say, schooling are included -- and particularly where the data are organized sequentially -- the coefficient of experienced mortality expresses mostly a replacement mechanism. If hoarding is important, then in a cross-section of countries the coefficients of mortality should be larger (in absolute terms) than those of the household studies; and in household studies the coefficient of experienced mortality should be greatly affected by introduction of those other variables. (For a recent attempt to identify hoarding by direct questions on expected mortality see Heer and Wu 1975).

RIGID AND REVISED TARGETS

The simple way of looking at child mortality and fertility is to take a given objective in terms of desired number of children (or sons) and ask how many births are required to attain (at least) this number of surviving children (with a given level of certainty). The level of experienced or expected child mortality may also affect the target, and the relationship between fertility and child mortality is the net outcome of the effect of mortality on the desired number (or rather profile) of surviving children and the effect of mortality on the number of births necessary to reach the target.

The *experience* of child mortality by itself is analogous to a loss of real income. This loss is likely to increase with the age of the child at death. Targets would be revised according to the relevant income elasticities. The less income elastic the demand for children (and the lower the income loss associated with the death), the more complete should replacement be. Less than full replacement may occur near the attainment of the (revised) desired number of surviving children, or, more likely, the revision may be distributed over the life cycle letting the whole time profile of surviving children absorb the downward revision. Some evidence for that is provided in Rutstein 1974 and Ben-Porath, 1976b.

Expected mortality affects the price of children and generates both an income and a substitution effect against (surviving) children. If children were to die only after the full parental expenditure on them has been made, then we could say that the elasticity of the number of births with respect to the survival rate (η_{ns}) equals $-(1 + \eta_{n\pi})$ where $\eta_{n\pi}$ is the demand elasticity for children. This would mean that if the demand for children has an elasticity larger than unity, the response of fertility to increased survival would be direct because the increased demand for survivors increases births by more than the decline in the number of births necessary for one survivor. If we remind ourselves, however, that most of child mortality is infant mortality and only a fraction γ of expenditures on children who would survive is spent on children who do not survive, then this equation becomes $\eta_{ns} = -(1 + \eta_{n\pi}\gamma)$ which implies that the elasticity of demand will have to be larger (in absolute terms) than $1/\gamma$ in order for fertility to respond favorably to increased survival (declining mortality). For reasonable values of γ the demand for children is not likely to be elastic enough for this condition to be fulfilled. (Incidentally, this would mean that it is incorrect to infer from an inverse relationship between fertility and mortality that the demand for children is inelastic.)

All this rests on the premise that the demand for surviving children in fact will rise when child mortality declines, which is sort of inescapable if expenditures on children are treated as an exogenous price.

However, this is not clear, if, as argued by O'Hara (1972) and others, there is a substitution from numbers of children to quality, as mortality declines; or as argued by Kuznets (1973, 1974), there is a shift from human lottery to human capital. Under certain conditions, it is then possible, but not necessary, that the demand for *surviving* children will decline as mortality declines.[2] It may be reasonable to suggest that the revisions of desired number of surviving children that are related to changing expenditure patterns lag behind this more "technical" response.

The pure effects of uncertainty that is associated with high child mortality are difficult to tackle. An attempt to guarantee a given number of survivors is associated, as already indicated, with greater risks concerning the consumption levels of the parents and the children, so that it may reduce the demand for children relative to what it otherwise would be unless demand is indeed asymmetrically biased towards "at least" a given number of children. Note however that where high mortality prevails, other risks are greater, so nothing firm can be said here.

PARTIAL VERSUS GLOBAL EFFECTS

The discussion of the effects of infant or child mortality on fertility in most micro data (including this study) does not explicitly deal with some associated developments that may lead to quantitative discrepancies -- maybe even to the extent of a change in direction -- between the temporal relationships and the partial cross-section estimates.

Although the trends of declining mortality do not occur uniformly along the age profile of mortality, the rapid declines in mortality that have occurred in LDCs in the last few decades have not been confined to children (see Stolnitz, 1974). The increase in parental life expectancy, unlike the increase in the survival of children, is on the whole likely to be pronatal. First, supply considerations: fewer mothers die when they are still in the child-bearing period, fewer marriages are dissolved by the husband's death, and thus the loss of time between marriages or early cessation of pregnancies due to widowhood are reduced (see Ryder, 1973). Parental health that improves with declining mortality may increase fecundity (see U.N., 1974, and Stolnitz, 1974, Sheps, et al., 1965) Second, demand considerations: the discussion of old age support is couched in terms of the question how many births are required to guarantee at least one son for the father when he is, say, 65. Whatever the merits of this statement, its implications for demand surely depend on the probability that the father will survive to age 65. As mortality declines, the probability that children will survive to a *given* parental age rises more than the probability that they will outlive their parents. As mortality declines some parents may be afraid that they will survive

their children. This issue is not just that of having one surviving supporter, but also of spreading the heavier burden of support implied by the longer period among more children. This is a partial effect and is likely to be less important in the long-run than the simultaneous decline in the desired number of surviving children and the rise in investment in human capital. But the timing of the responses may differ and we cannot rule out the possibility that at some initial phase the positive effects on demand would stand out.

Beyond this, we have the obvious problem of the correlation between the decline in mortality and other aspects of economic and social change. Other variables may either strengthen or eliminate the effect of declining mortality on fertility, and the relationship between mortality and other variables relevant for fertility varies over time and place and may be different in cross-section data and time series data.

REVERSE CAUSALITY

The death of children is not given to the families but rather is a result of behavior. Parents have discretion as to the amount of care devoted to children to protect them from the common causes of death, in particular those that are associated with gastric illnesses. The endogenous element in the decline in child mortality in Europe may have been substantial (see Shorter 1935). In our data there is a strong relationship between child mortality and parental schooling. (We have examples of increased child mortality when women have left the house for work and left infant care to the older children.) In some cases infant mortality is just another way of regulating family size, where the control of the number of pregnancies is complicated. Thus, families who find themselves with more children than they want would let excess infants die off. Except for some cursory remarks, I shall not deal with this possibility here. (See Kelley, 1976.)

BEHAVIOR VERSUS PHYSIOLOGY

In the economic-demographic literature there is a distinction between demand and supply factors in the explanation of fertility (see, e.g.,

Easterlin, 1975). Sometimes biological or physiological factors are the dominant determinant of fertility -- natural fertility being the effective constraint on the number of births. The post-partum sterility accompanying lactation reduces the number of possible pregnancies. Infant mortality and the interruption of breast feeding raises the possible number of pregnancies and perhaps the number of live births. (See e.g. Knodel 1963, Jain et al. 1970). When fewer children are desired than would result from uncontrolled fertility the explanation of fertility response to child mortality must be sought within a demand framework. In the grey area between supply and demand there are social customs that may act as constraints on individual behavior but which are in the long run themselves shaped by the needs of individuals. Breast-feeding customs may belong here and thus the effect of mortality on fertility via lactation may in part depend on demand considerations. In general we can assume that in populations of low fertility demand considerations are dominant. It is hard to distinguish between supply and demand factors in populations that have high fertility.

However, the issue is broader than that. The incidence of child mortality is likely to be correlated with nutrition and health of the mother which in turn may affect fecundability. Age at menarch is associated with levels of nutrition, certain diseases affect fecundity within marriage, and pregnancy wastage. There is no reason to assume that there is some stable relationship between all these supply effects. It could well be that measures that result in a decline in child death rates affect fecundability directly more in some situations than others. As will be seen later this is an issue of some importance in the present context.

III. MICRO CROSS-SECTION DATA OF THE 1961 CENSUS

The Israel 1961 census of population included a 20-percent sample of households for which a detailed questionnaire on economic and demographic matters was completed. The unique feature of this population is that most of the adult women were foreign-born and that there is a large population of women who were married before immigration and had had some children abroad. Sample size is large enough to allow separate analyses by woman's country of birth, thus providing the opportunity to do a quasi-international study with a homogeneous body of data. The important pieces of information for our purposes are the number of births that took place in Israel (BIS), the number of births abroad (BAB) (prior to immigration), and the number of children born abroad who died before they were five years old (DAB). We know the woman's age when she immigrated and her age at the time of the census; there is no information on the age and sex of the children.

The population considered covers a broad spectrum of countries of origin. Immigration from Asia and Africa was mostly from the Arab countries of the Middle East and North Africa and from Turkey andIran, with mean levels of completed fertility abroad of approximately 6-7 children of which approximately one out of three or four died by the age of 5. The immigrant classified here as Europe and America are mostly from Eastern and Central Europe with completed fertility abroad of 2-3, of which one in seven or eight died by the age of five. Large although somewhat narrower differences are also present in fertility in Israel after immigration.

We can get an initial impression of the mortality-fertility relationship by examining a cross-tabulation of births in Israel by age at immigration and the number of births and deaths that occurred abroad, distinguishing between immigrants from countries in Asia and Africa and those from countries in Europe and America (Table 1). The number 0.933 in the column headed 2 and the row 2-1 means that women who were 25-29 of age when immigrated and who had had 2 births abroad (BAB), had 0.933 more children in Israel (ΔBIS) if 2 of their children died abroad rather than one (2-1). What emerges from the table is the following: (a) women with a given number of births abroad (BAB) had more children in Israel if they lost one or more of the children

born abroad; (b) the response of fertility to child mortality is in some cases greater than unity, particularly among young women and at low birth orders; (c) the response particularly to the death of one child, tend to be lower for women who were past the mid-thirties when they immigrated; (d) given the woman's age at immigration, the response to a death is lower, the greater the number of births she had had before immigration; (e) the response to the second or third death of a child is often negative; (f) the response of women born in Asia-Africa (AA) is greater than that of women born in Europe-America (EA).

I am not concerned here mainly with examining the determinants of desired fertility but rather with the effect of child mortality on fertility. Still, it is impossible to ignore the fact that there are joint determinants of both that may create an inflated impression of the effect of one upon the other (even if we go on ignoring the possible causality from fertility to mortality).

The equations estimated include schooling categories of the mother (dummy variables), indication of the place of birth of the mother (continent or country) and age variables (age at immigration and age at the time of the census). The age variables are not attached to the occurrence of a vital event; absence of such information is a drawback of this body of data.

Deaths abroad (DAB) and births abroad (BAB) are introduced into two functional forms: a free form discrete interaction model (Model I) (with separate dummy variable for each DAB BAB combination) and a restricted continuous interaction form (Model II).[3]

There is no control for child mortality in Israel. The level of child mortality in Israel has been very low, but it is quite clear that it is correlated with child mortality abroad so that its absence can generate an upward bias in the coefficient of DAB.

Source: Based on unpublished CBS data from the 1961 Census of Population

In Table 2 results of Model I are presented for women who were 30-34 at immigration and above 40 in 1961, classified to two categories of place of birth. There is some reduction in the estimated "effect" of mortality on fertility compared to the tabulations, but essentially the same picture remains true, (in spite of the fact that women's education is correlated with fertility and child mortality).

The aggregation of all countries of origin by continents may be too crude given the heterogeneity of the individual countries. Looking now at all women who immigrated when they were ages 15-49 and running regressions separately for each country, pooled with dummy variables for each country and pooled without dummy variables, we see that the country differences turn out to be statistically significant.[4] Most of the country differences are captured by the dummy variables although the contribution of separate coefficients by country is statistically significant. (This is based upon Model II.)

Examining both the regression coefficients and the derivatives of BIS with respect to DAB, we find (Table 3) that (a) the responses to DAB and BAB are significant and in the expected direction in both continent groups (AA and EA); (b) there is a negative interaction between BAB and DAB which implies that the response of births in Israel to child mortality abroad is smaller, the greater the number of births abroad; (c) for any given BAB and DAB combination the response to child deaths abroad is greater among AA women than among EA women, but if we calculate the response close to the mean level of fertility (BAB = 4 for AA and BAB = 2 for EA) the response of EA women is slightly higher (because of the significant interaction between BAB and DAB); (d) the country dummy variables in the pooled regression indicate that women from Libya and Algeria and Tunisia have significantly higher and women from Egypt significantly lower fertility in Israel than would be indicated by their experience abroad, education, and age (there is some variation in EA as well); (e) the response to child deaths around mean fertility is in the range 0.3 - 0.5 in the individual Asia-Africa countries, and goes up to 0.6 in EA. All these magnitudes are somewhat higher in the regressions confined to women

aged 30-34 at immigration and aged 40+ in 1961, ranging from 0.35 to 0.71 for AA and going up to 0.8 for EA (now shown). Model I, which, as in Table 2, does not constrain the functional form of the interaction (see Table A-1) was run separately for each country and shows that the response to one death in the low birth orders is in some countries above one. (f) the magnitude of the coefficient of experienced mortality in the regressions for the continents is not larger than in regressions for individual countries.

What do these findings suggest? The similarity between magnitude in the pooled and country regressions may be interpreted to mean one of two things: 1) Hoarding is not that important; this is based on the conjecture that expected mortality should be more closely associated with experienced mortality across countries than across individuals in the same country. 2) Given that the dependent variable is fertility in Israel, in a regime of much lower and uniform child mortality, past experience has been discarded as a predictor of future survival.

The fact that even the low fertility immigrants from Europe show a high response indicates that demand based mechanisms are quite important. It may still be true that supply mechanisms are important in the Asian and African populations, and this may explain the somewhat higher coefficient (per parity) in AA. The variation in coefficients among individual countries is not consistent with the U-shaped relationships observed by Preston (1975b) as one moves from what he describes as supply dominated to imperfect demand control to efficient planning societies.

Why does the estimated response decline from full (or more) replacement as the number of births abroad rises? Women with births abroad consist of those who had fewer children than they would have liked (at that phase of their life cycle), those who had exactly the number of children they wanted, and those who had more children than they would have liked. The first group would want to replace deceased children fully and will do so unless there are constraints operating from the supply side

(fecundity, health, etc.); if child death by itself relaxes a supply constraint (the lactation effect) those below desired fertility would respond fully. Those who are close to the optimum may revise the desired number of children downward (see Section I) and this may result in less than full replacement. Those who have more children than they want would not replace deceased children. When the data are controlled for some exogenous determinants of fertility and the women are grouped by the actual number of children, the proportion of those with excess fertility increases with the number of births. The random element in fertility should lower the estimated response. If those at low birth orders are not constrained in replacing deceased children, the major reason for lack of response is excess fertility, and thus the coefficient should decline with the number of children. Also, a greater number of births may already include a pre-immigration response; in fact, the quicker the response, the less likely it is to be reflected in births in Israel.

This is also related to the age pattern of response. What we observe is that women who immigrated in their forties, particularly from EA, have a lower coefficient of BIS on DAB. This seems to contradict the hypothesis that women approaching the end of their child-bearing period would be more responsive to child death. A reason for this could be that early child deaths have been replaced abroad. In another book of data where the birth order of the deceased children was known and the subsequent stopping probabilities and birth intervals could be observed (for EA) I found a stronger response of older than of younger women. (See Ben-Porath, 1976b).

Just in passing we can ask how do these results fit the reverse causality -- i.e. the view that more children die when there are more births. Given that births in Israel are subsequent to deaths abroad, they would be correlated according to this view only if people who expect

to have higher future fertility (while in Israel) are particularly negligent of their earlier children (while abroad). This is, to say the least, unlikely.

There is another finding worth stressing: in the free-form interaction model (Model I), cases with more than two deaths are often associated with *lower* births in Israel than cases with less (or no) child mortality. (This was also found in the Taiwanese data by Heer and Wu 1975). Let me suggest two possible explanations: a demand-based view would suggest that those who experience child mortality beyond the common experience of their environment may "learn" from their experience and give up trying. There may however be a supply consideration. Generally, in discussing micro data there is a tendency to emphasize physiological and environmental factors that induce a *direct* relationship between child mortality and fertility. The termination of post-partum sterility is an explicitly causal factor. In addition, there may be correlation across households between the ability to keep children alive and the ability to control family size. There may however be health and physiological factors that reduce both infant and prenatal mortality. The history of pregnancies terminated without the birth of a live child is not well documented and only sparsely researched, but there is evidence that (apart from stillbirths) a large proportion of pregnancies do not come to term and it seems quite reasonable that there are both physiological and environmental causes common to both prenatal and postnatal mortality.[5] This is in fact a major line that will be followed, unfortunately, only speculatively, later.

IV. FERTILITY AND MORTALITY OVER TIME

In this Section, I try to infer the temporal aggregate movements in fertility and child mortality from more or less the same data. These developments fall into two phases: (a) changes that had occurred in the country of birth; and (b) changes associated with immigration to Israel. I concentrate on the Asia-Africa immigrants, since the second world war and its atrocities complicate a temporal analysis of the Europe-America immigrants.

TEMPORAL CHANGES IN FERTILITY AND MORTALITY IN THE COUNTRIES OF BIRTH

The main source used to trace the movements over time abroad is again the 1961 census of population of Israel.[6] Tabulations of fertility abroad and child mortality abroad by woman's age at immigration, period of immigration, or age at the time of the census (1961) can provide a basis for some inferences concerning temporal movements prior to immigration. The drawbacks of such a procedure are obvious; first, births in general and particularly births of children who did not survive are likely to be under-reported, particularly by older women. This can reduce or even eliminate a downward trend in both fertility and child mortality; second, even if the data can give a reasonable picture of the immigrant population, it may not be a proper representation of the Jewish communities in the country of origin. In comparing immigrants of different periods it seems that individual choice and selection were less important in the period 1948-1961 than in either prior or subsequent waves of immigration. In relative terms emigration in this period involved whole communities, complete families, and greater predominance of Israel as a destination. But even here selectivity bias cannot be ruled out.

Let us now examine the evidence by period of immigration and age at immigration. By observing women of a given age at immigration we control the life-cycle phase; differences in period of immigration translate into

chronological time of birth. There is at least one other selectivity problem -- we are dealing with women who were married abroad when they immigrated, married once, and were still married at the time of the census. Given the variance in the age of marriage and the close relationship between fertility and duration of marriage, women who were young and already married at the time of immigration have more children than would be representative of the cohort as a whole.

The data for immigrants from Asia and Africa taken as a group (Tables 4 and A-2) indicate that there has been a downward trend in child mortality abroad; and that this decline probably started some time in the early 1940s. This is based on the following observations: holding age-at-immigration constant, the more recent immigrants report lower child mortality abroad compared with earlier immigrants. The differential is the greatest and extends over the longest period of some twenty years for women aged less than 25 when they immigrated: while those immigrating in the early 1940s report a loss of around one out of three or four children, those who immigrated in the late 1950s report a loss of one child in eight. Among women who were older at immigration, the differentials between birth cohorts (or immigration cohorts) are smaller, reflecting the fact that more of their children were born when mortality was higher (there is always the possibility that the older women under-reported child mortality and births).[7]

This description rests on an aggregation of immigrants from AA countries that differ from each other. Because of the small number of observations we can get only a tentative picture of individual countries. The reported child death rate in Yemen and Aden is over 40 percent and there seems to be no downward trend in it. The other Asian countries report rates half or somewhat less than half of this figure and there seems to be a (somewhat blurred) moderate trend of decline. In North Africa, Egypt, with a Jewish community partly of European origin, has the lowest child mortality. Mortality in the other North African countries (Morocco and Tangier, Algeria and Tunisia, Libya) is higher than in the countries of the Middle East; the decline in the death rate in North Africa (with the possible exception of Libya but

SOURCE: Table A-2.

including Egypt) is steeper than in the Middle East. What is here said about *trends* in individual countries is partly based on the difference between countries in the cross-section variation of the child death rates by age at immigration, holding constant the *period* of immigration (1948-54, see Table A-3). While in a single cross-section age differentials confound life cycle with temporal variations, the differences between countries probably reflect differences in the time trends (the typical curve relating infant mortality to age of mother is J-shaped with a trough at the early twenties; see, e.g., Legg, et al., 1969).

Let us turn now to the evidence on fertility, looking first at the number of children born abroad (Tables 4 and A-2) by period of immigration and age at immigration, one can see a slight decline from the early to the late 1950s. The immigrants of the period before the 1950s report in many cases lower fertility abroad than those of recent periods. This could reflect a real increase in fertility abroad, but could also be due to changes in the selection of immigrants from the original population and to a downward bias in reporting early fertility. A recent retrospective study of marriage cohorts also found that AA women who married before the late 1940s had lower fertility, with duration of marriage held constant, than those who married later (see CBS, 1976). In any case, there is little evidence in the by-continent aggregation of any tendency for fertility to decline to match the decline in mortality.

In individual countries, Iraq is the only one for which three 5-year means show a consistent downward trend in fertility; in Libya and Algeria and Tunisia there is a tendency to decline over two 5-year means.

Table 5 relates fertility and mortality levels across countries: Turkey, Syria and Lebanon, and Egypt are relatively low both in fertility and in mortality. The fertility ranking between the middle and the top mortality levels is not unambiguous. Yemen, with at least twice the mortality of any other country has a fertility level below that of Morocco and Algeria and Libya.

Note that inter-country differences in fertility are closely associated with woman's age at marriage, as indicated by the percentage of

Table 5. Fertility, Child Mortality, and Early Marriage: Selected Countries in Asia-Africa[a/] Women age 40-44 at immigration

women married abroad who married under 17 (Table 5). The simple correlations across countries are 0.64 between the number of children born and the percentage deceased; 0.81 between number of children and age at marriage; and 0.59 between percentage deceased and age at marriage. I draw attention to this relationship because if there is a relationship between desired fertility and child mortality, to the extent that it operates via age at marriage, it *must* be a relationship between desired fertility and *expected* -- as distinct from *experienced* -- child mortality.

CHANGES IN FERTILITY FOLLOWING IMMIGRATION -- AGGREGATE FIGURES

Immigration was associated with a dramatic change in environment and conditions. The extent of the changes varied depending on when and where the immigrants came from. As already indicated, there were differences among the immigrants from Asia and Africa, and correspondingly this would mean that the impact of immigration could differ (the economic and social gap between the Jews coming from Alexandria or Baghdad and those coming from Yemen was no less than the gap that many of the immigrants faced by immigrating). Note also that the largest wave of immigration that occurred in 1948-1951 (known as the period of mass-immigration) was very large relative to the original population (population almost doubled in this short period), and constituted a large pressure on resources, so that immigration was not an immediate jump to the mean per capita income of a semi-developed country. For many of the immigrants the initial period of residence in Israel was associated with poor housing conditions in camps of temporary huts and with significant amount of unemployment. Others were settled on the land and got their income from public employment projects. It is impossible to judge what was their realized real income and what is more important, what were their expectations initially concerning their future material well-being. Subsequent years have seen rising incomes, improved housing, increased labor force participation of women and other corollaries of participation in a rapid development process. The issues that matter here are the differential timing in realization of the change in income, the change in price of children (and their schooling and health) and the timing in changes in the supply of births.

Total fertility for women born in Asia and Africa declined (except for a slight rise at the period of mass immigration, when new immigrants with high fertility were added en masse to the small community of longer residence and low fertility (see Table A-4)). Child infant mortality declined (see Tables 10 and A-6). What would be desirable is to follow the changing behavior associated with immigration of women at different phases of their own and the family life cycle -- unmarried, married abroad, married with children born abroad, and at various ages at immigration. But we do not have the means to follow the process of adjusting to this sudden change in the necessary detail.

Let us first consider women married before immigration (and in most cases with some children born abroad). We know the number of children by woman's age in 1961 and also the number of children born abroad, so that we know how many were born in Israel and can calculate a rough measure of children born per year of residence in Israel. The birth rate abroad can be inferred from the difference in the number of children born to women of different ages who immigrated in a given period. If fertility abroad has tended to decline these differences would give an *upward* biased estimate of the birth rate abroad; and if fertility abroad has risen, these rates would give an underestimate. The rates will likewise be underestimated to the extent that older women under-report births.

Table 6 leads to the following observations:

1. The total number of children born to women married abroad and aged j years in 1961 (the date of the census) is generally higher than that born abroad to women aged j years at immigration [compare lines (i) and (ii) in Table A-5].

2. Correspondingly, births per year of residence in Israel of foreign-born women married abroad is higher than births per year abroad, even for women coming from countries of very high fertility.

3. The increase in fertility (in Israel compared with abroad) is general (over countries) and substantial for women who were relatively young at the time of immigration.

4. There is a somewhat blurred picture as to the cross-over age -- the age at immigration at which women reduce rather than raise fertility

after immigration. In Table 6 the underlined figures indicate the cross-over ages. The younger cross-over ages are found in the countries with the lowest child mortality (of those listed), Egypt and Turkey. The highest cross-over age (and it is not clear that there is a cross-over at all) is for Yemen and Aden and Libya, the countries with the highest rates of child mortality abroad.

5. There is some evidence (in a calculation similar to that of Table 6, based on somewhat different tabulations) that immigrants from a given country who came after 1955 had more births per year by 1961 than those who came in 1948-1954 (in Table 6 this is so for Morocco and Tangier but not for Egypt and Sudan).

Table 7. Annual Percentages of Changes in Total Fertility in Israel, Selected Period of Immigration

Immigrant of the Period	End Points for Calculated Change	Women Born In: Asia & Africa — Of Specified Period	Asia & Africa — All	Europe & America — Of Specified Period	Europe & America — All

1955-1960	1968-1971	-4.2	-1.6	7.2	3.6
1961-1964	1969-1974	-5.3	-2.5	-1.4	0.1

SOURCE: Table A-4 annual rates are calculated for end points of the designated period. In the case of the immigrants classified to sub-periods 1961 is the average for 1960, 1961, 1962.

Let me note several possible biases in these calculations: If fertility abroad has tended to decline these differences would give an *upward* biased estimate of the birth rate abroad; and if fertility abroad has risen, these rates would give an underestimate. The rates will likewise be underestimated to the extent that older women under-report births.

It can be argued that the phenomenon to which we point, namely the increased fertility after immigration, reflects the fact that immigration is associated with postponed fertility, so that pre-immigration fertility is depressed and post-immigration fertility exaggerated. The procedure used for estimating fertility rates abroad by taking *differences* in number of children born abroad between women of different age-at-immigration is likely to avoid this problem. Fertility rates in Israel however could in principle reflect such possible postponement effects. We would get these results artificially if women were systematically classifying births that occurred abroad as if they occurred in Israel, but I do not see a reason to assume so. Dr. Van der Walle raised the possibility that women who were older at immigration could have had lower marriage duration than the selected group of those who were already married when they immigrated at a younger age. This would indeed bias downward the estimated birth rates abroad. Given, however, that marriage abroad occurred at a very young age this could apply only to the very young. Also, looking at the immigrants from all of Asia and Africa we can control for duration of marriage: In Table 8 we compare first all of the total number of births abroad by duration of marriage for women married abroad, by age at immigration (lines 3) with the number of births (in Israel and abroad), by age in 1961 (lines 2). The latter figure is consistently and significantly higher and indicates that per year of marriage, fertility in Israel of AA women married abroad was significantly higher than it was abroad.[8]

Admitting the possible biases, and noting the unusual pattern of the implied birth rates by age, I still tend to regard the phenomenon described as a real one.

It is interesting to consider the women who married in Israel. The control for duration of marriage is admittedly imperfect (the 5-year interval may be too crude); subject to this qualification we see that in the first decade of marriage, the fertility of women who married in Israel

(lines 1) Table 8 is *higher* than the fertility abroad of women of the same age (lines 3) and lower than fertility (including fertility in Israel) of those married abroad (lines 2).

We do not have an unbiased way of inferring the change in the marriage age following immigration. There is however enough indication to believe that the picture of rising age at marriage (Table A-8) although exaggerated, does point in the right direction. If this is so we can summarize the picture in the following way:

(a) foreign-born women who came to Israel unmarried curtailed early marriage and raised the average age at marriage; (b) within marriage, fertility is somewhat higher in the first few years than it was abroad for women who married abroad; limitation of family size then sets in; (c) women who married abroad and immigrated to Israel relatively young increased the number of births immediately after immigration and then reduced fertility gradually; (d) women close to the end of the child-bearing period tended to reduce fertility after immigration; the evidence for this is however somewhat ambiguous. The rates of decline of fertility of a given immigration cohort will be above or below the rate of decline for the total depending on how recent was immigration compared to the recency of arrival of other immigrants (see Table 7).

I have refrained so far from discussing the experience of the immigrants from Europe-America (mostly Europe). Fertility before immigration was much lower than in the countries of Asia-Africa. Child mortality was also lower, but by no means negligible. Those who immigrated in 1948-1954 were mostly survivors of the holocaust. Their marital histories were disturbed and interrupted; child mortality was also a result of war and atrocities. Calculations analogous to those shown above indicate that EA women also experienced a rise in fertility after immigration. But fertility does not decline sharply. In the case of EA women there is more reason to believe that pre-immigration fertility was abnormally low. There has been some decline in period fertility rates of European-born women in Israel and then some increase. On the whole, higher levels of fertility than those experienced abroad were sustained.

V. CAN THINGS BE FITTED TOGETHER?

The cross-section micro data indicated a strong direct relationship between child mortality abroad and fertility in Israel. They also indicated that response in terms of fertility in Israel is weaker among those who immigrated with many children and those who immigrated relatively old and is often negative among those who lost many children. The significant direct relationship between child mortality and fertility would lead us to expect a downward trend in fertility abroad, for those periods and countries where child mortality declined, and a decline in fertility after immigration as a consequence of the sharply reduced child mortality.

When the same data were aggregated in order to unravel the relationships, we observed a little and unstable decline in fertility accompanying decline in child deaths abroad. Subject to qualifications stemming from possible biases in the data there is some possibility that fertility had even increased in the past. More interesting and clear is the finding that, following immigration, young foreign-born women who married abroad first increased fertility and then gradually reduced it; this was not always true if they immigrated in their late thirties or forties. Those who immigrated unmarried postponed marriage in Israel, started their married life with a high level of fertility, and then reduced it after only a few years of marriage.

It may be relevant to bring in at this point the experience of the Arab population of Israel. This group experienced very high and declining levels of infant and child mortality in the period of the British Mandate. The Arabs who lived in Israel also experienced rapidly declining mortality after 1948 (see Table 9). The fertility of the Arab population has however increased from the British to the Israeli period and during the Israeli period. The Moslems, who constitute approximately two-thirds of the Israeli Arabs, increased fertility steadily for several decades, from around 6 in the late 1920s, 7 in the mid-1930s and 1940s (Central

Bureau for Medical Statistics, 1945), to reach a peak of close to 10 in the mid-1960s; it is only in the last decade that they have reduced fertility. Among the Christian Arabs, the decline in fertility began earlier.

Even when one is dealing with a single group of people, so that there is no change in personal characteristics, immigration entails a dramatic change in environment, personal conditions, and expectations. The response to the different aspects of the change may however vary. If one looks only at the time series of total fertility in Israel of AA women, the trend is downward as would be expected on the basis of several reasons including lower child mortality. The surprise is in the initial increase in fertility immediately after immigration, and the question is what could cause this burst and why it is so pronounced among the younger women.

Here I would start speculating about health rather than behavior. Immigration meant a shift to a different public health system. This was very quickly reflected in low child mortality rates, but it presumably also affected the health of women in and out of pregnancy. The improvement in health services and nutrition could have some effect on fecundability, at least among the most undernourished immigrants (Yemen and Aden). There also seems to be room for an increase in the number of births out of a given number of pregnancies through a reduction in pregnancy wastage of various sorts. (See Bierman et al., 1965.) Some nutritional and behavioral habits that reduce prenatal waste are transferable and are not predetermined by the mother's "permanent" characteristics. One hypothesis is that immigration was followed by a decline in both child mortality and prenatal wastage, so that initially the same number of pregnancies resulted in more live births. To the extent that women were previously constrained by the supply of birth then one can see why the initial increase in supply would be welcome before desired family size is revised down. But even if this was not the case, the downward adjustment in fertility which is supposed to reflect replacement would have required an even larger reduction in pregnancies to compensate for the increase in successful pregnancies, or for a means of inducing abortion, and one could see why this would not be instantaneous.

Induced abortion has probably been the most important means of controlling family size in Israel, and is also prevalent among AA women. (This may be the closest substitute for natural abortion and has the advantage over the then most popular preventative method that it does not depend on the husband.) There is however no strong evidence on the nature of the pre and post birth mortality correlations that would support this particular emphasis.

Can this hypothesis account for the fact that the increase in fertility after immigration was marked in the young age groups and may not have occurred among older women of child-bearing age? Two things might be at work here: Older women may have found it easier to reduce the frequencies of pregnancies. On the other hand, for older women who came with a large stock of children who survived, the new realities of low child mortality had much more immediate consequences in terms of family size. Younger women could borrow from the future by allowing themselves higher fertility as long as they were below their desired completed family size. Potentially, older women had more room for increasing on successful pregnancies; the question is whether they would be responsive to the changed health regime.

What we are examining is the possibility that the health measures which affected mortality were associated with health developments which increased fertility; this possibility is consistent with the before-and-after immigration experience, with the experience of the Arab population, and perhaps with the experience of immigrants over time abroad. While we do not have a direct test of this hypothesis; let us examine some child mortality data to see whether they can provide some support for it.

The decline in child mortality over time has the following features (Table 10)[9]: (1) neonatal, postneonatal and perinatal mortality all declined; (2) infant mortality declined relatively more than perinatal mortality; (3) within infant mortality the steepest decline in the period as a whole is in mortality after the first month of life (which declined to between one-quarter and one-fifth of its initial level). In the early 1950s, i.e., immediately following the period of mass immigration the decline in perinatal mortality was as large as in postneonatal mortality. This would be sympathetic (to use a weak term) to the speculation offered here. Comparing

Table 10. Infant Mortality, Perinatal Mortality, and Late Fetal Deaths: 1948-70

(rate per 1000 live births)

	Infant mortality				Late fetal deaths	Perinatal mortality
	Total (2)+(3)+(4)	1-11 months	7-27 days	0-6 days		(4)+(5)
	(1)	(2)	(3)	(4)	(5)	(6)
1948	36.3	..	..	..	14.9	..

Source: CBS, *op. cit.*, (1974), p. 112, Table 1.

child mortality by mother's continent of birth in 1952 and 1960-1963 we again observe that (4) the decline in postneonatal mortality is the most marked in both continent groups (Table A-6). Also, the only important differences *between* continents are in postneonatal mortality; (5) the decline in deaths from infectious diseases, pneumonia, and gastro-enteritis is the main cause of the decline in infant mortality. The data by continent of birth do not reflect the early relative decline in perinatal mortality, which had already occurred by 1952 and the comparison between the continents does not provide support for this speculation.

Is there a demand-behavior explanation for the short-term rise in fertility and the subsequent decline? A reasonable speculation would be to argue that a pronatal income effect precedes the adjustment in the elements of the economic changes in the life of parents and their aspirations for their children that generate antinatal substitution effects. As indicated, we do not have a well-defined picture of actual real income of immigrants immediately following immigration. If a direct income effect is to be invoked, it must rely on the revision of permanent income on the hopes that immigrants had for the new phase in their lives. Such an income effect would indeed be more powerful for younger than older women and would, thus, be consistent with the age patterns observed.

With respect to the Moslem population, we have a longer period of rising fertility and of rising incomes, and there is some indirect support to the lag in the emergence of fertility reducing variables. (See Ben-Porath, 1972).

What implications does the temporal phenomenon have for the cross-section findings? In discussing the cross-section results I partly ignored the fact that we are relating fertility in Israel, occurring under conditions of much lower child mortality, to prior differences in child mortality and fertility abroad. There has been a downward *convergence* of child mortality in Israel. Thus, higher child mortality abroad is

associated with steeper declines in child mortality: higher fertility in Israel, given the number of births abroad, means greater increase in fertility (in Israel compared with abroad). It is thus possible that what we have estimated is a mixture of the positive replacement effect of child deaths on fertility, with the positive effect on fertility of factors associated with the *decline* in child mortality. This could explain the presence of coefficients greater than unity in the Asia-Africa countries. The smaller response in the cross-section study observed for older women would again be consistent with the temporal finding that older women did not increase fertility after immigration. I should mention that a study based on another body of data in which behavior following each birth was analyzed depending on whether the child survived or not resulted in somewhat smaller responses than those observed here (Ben-Porath, 1976b).

VI. SUMMARY

This paper poses some of the issues relating to the relationship between child mortality and fertility and then examines the fertility-mortality relationship of mostly foreign-born women in Israel, women who immigrated from various countries in Asia, Africa and Europe and continued child bearing in Israel. The marriages between questions of general interest and the experience of a very particular population, coupled with methodological problems means not only that these findings do not settle the questions with which one started, but that the road to generalizations may be obscured. There is, however, a potential gain from the diversity in background of immigrants, the non-marginal nature of the changes associated with immigration, the unusual configuration and timing of various corollaries of economic and social development, coupled with a uniform set of data.

Among the general issues that I listed, in Section V a major one is the distinction between response to the experience of child mortality (replacement) versus the response to expected mortality (hoarding). This distinction is important both with respect to the magnitude and promptness of the responses. Some of the other issues are the distinction between behavioral and physiological mechanisms, the degree to which child mortality affects the desired number of surviving children, and the effect of other variables correlated with the decline in fertility affecting either the demand of the supply of births and children.

The cross-section phase of the study consists of regressions of fertility in Israel as a function of fertility and mortality abroad, education and age variables. The regressions were run by separate countries of origin and pooled for Asia and Africa and Europe. Fairly sizeable coefficients of child mortality on fertility were estimated. The presence of such effects among the immigrants from Europe suggests the importance of the behavioral mechanism. The strong effect among the high fertility immigrants from Asia-Africa may be partly reflections of a supply mechanism.

The fact that the coefficients in inter-country regressions were not higher than in the country regressions is considered evidence against the hoarding

hypothesis (based on the supposition that the inter-country differences in expected mortality are more strongly correlated with experienced mortality than the intra-country differences). The weakness in replacement among older women in this particular study (unlike another body of data describing Israeli women) is taken here to result from fairly quick replacement response abroad.

Viewing the same data for inferences concerning what happened over time, we concluded that 1) in the countries of origin there had been a decline in child mortality without appreciable decline in fertility, 2) immigration was followed quickly by drastically declining mortality, but fertility initially rose above its pre-immigration levels 3) beyond the initial stage, fertility of Israeli women married abroad declined, and there has been also postponed marriages of unmarried immigrants and decline in their fertility after the first years of marriage. The increase in fertility following immigrations, as well as the rising fertility over time of Moslems (in face of declining child mortality) suggest that the discrepancy between the cross-section and time series relationship between fertility and mortality (i.e. the sluggish aggregate response compared to large cross-section coefficients) may arise from the operation of other variables in the two contexts rather than from the slow revisions of expectations concerning child mortality, as part of a hoarding mechanism.

In speculating about the nature of the phenomena that delay the effect of replacement, I mention the possibility that income effects (associated with immigration in the case of the Jews) may precede in time the adjustment in life style and aspirations that generate the fertility-depressing substitution effects. Alternatively, it is being argued that correlated with the same factors that reduced fertility over time there were health developments that increased the supply of births, possibly by reducing various forms pregnancy wastage.

What is required to sustain the latter hypothesis is to argue that temporally, either in the before-and-after immigration comparison or in some phases of the temporal decline in child mortality, the factors that determine child mortality and those that determine prenatal death

or involuntary sterility are correlated with one another more closely in the time series than in the cross-section.

It is not clear how implications can be carried over from a case of a sudden change associated with immigration from a less developed to semi-developed country to a process of gradual development. The experience of the Arab population in Israel is not inconsistent with the explanation presented here, so it may well be that in a more moderate way similar counteracting forces operate in a more usual LDC setting.

FOOTNOTES

[1]One should note of course that even with full replacement, halving of (e.g.) 200 per thousand child death rate would reduce a 45 per thousand birth rate to just 40 per thousand, and half replacement to 43 per thousand.

[2]Take a simple model where

(1) $$\text{Max } u[q(t, x)n, s]$$

$$\text{s.t. } \pi nx + s = y$$

where t = indicator of survival
n = number of children
q = index of child quality
s = consumption of parents
y = full family income
x = inputs into children
π = the price of one unit of x.

Both optimum quality of children, q^*, and optimum expenditure on them, x^*, can be solved as a function of survival (t). The solution of (1) is (2):

(2) $$\eta_{nt} = -\eta_{q^*t} + \eta_{n\pi}(\eta_{x^*t} - \eta_{q^*t}).$$

The first term represents a technical relationship -- as children survive longer, parents have more child services ($\eta_{q^*t} > 0$) and need fewer children for a given volume of child services. The second term represents the effect of prices and expenditure. The term $\eta_{x^*t} - \eta_{q^*t}$ is equal to the elasticity with respect to survival of expenditure per unit of quality, $\eta_{(x^*/q^*)t}$. This term is likely to be positive and thus contribute a downward slant to the fertility-survival relationships via the negative price elasticity (see also O'Hara 1972). If expenditure were independent of survival we would have the simple expression $\eta_{nt} = -(1 + \eta_{n\pi})\eta_{q^*t}$ which, like the analogous case of augmenting technical change, indicates that fertility will be directly associated with mortality if the demand for children is inelastic. (See Ben-Porath and Welch, 1975, and Ben-Porath, 1976b.)

[3]$$BIS = \alpha_1 DAB + \alpha_2(DAB)^2 + \alpha_3 BAB + \alpha_4(BAB)^2 + \alpha_5(BAB \times DAB) + \beta X$$

BIS the number of births that occurred in Israel.
BAB the number of births that occurred abroad.
DAB the number of deaths that occurred abroad.

$$\frac{\partial BIS}{\partial DAB} = \alpha_1 + 2\alpha_2 DAB + \alpha_5 BAB$$

4

Single regression	0.315		

[5]This possibility was suggested by Professors Davies and Halevi of the Department of Ecological Medicine, Hadassah Medical School, The Hebrew University.

[6]See Schmelz (1971) for a valuable compendium on child mortality of Jews in the Diaspora and for a description and evaluation of the child mortality data in the 1961 census.

[7] In retrospective data there are many problems associated both with the reported levels and with placing in time. In the Israeli census the distinction between children born abroad and children born in Israel is based on direct questions as to the number of children born in each place rather than an inference from matching birth rates of children and data of immigration. Age at immigration is a result of comparing year of birth and year of immigration.

[8] The gross difference in fertility between women grouped by age in 1961 and grouped by age at immigration is larger than the difference when we also control for duration of marriage. Average marriage duration is longer for the grouping by age in 1961, compared with the age-at-immigration grouping. Because 1961 is approximately one decade after mass immigration the women who married very young and immigrated soon after appear with long duration in 1961 and with short duration (and with younger age) when classified by age at immigration.

[9] We use the following definitions: stillbirths, born dead after 28 weeks of gestation; neonatal mortality, deaths in the first month of life; and perinatal mortality, the sum of stillbirths and deaths in the first week of life. Rates are per 1000 live births.

a/ b/ Notes on next page.

Table A-1 (contd).

a/ Foreign-born women, married abroad, married once, and with at least one birth abroad.

b/ Other variables in the regression are: woman's age at immigration, age in 1961, and years of schooling (six categories, dummy variables).

The figures are differences in the coefficients of dummy variables. Where no figure appears it is because at least one of the coefficients did not pass a critical (low) level of significance.
